University of California/Berkeley

Abstract

We present a novel lossless compression algorithm called Context Copy Combinatorial Code (C4), which integrates the advantages of two very disparate compression techniques: context-based modeling and Lempel-Ziv (LZ) style copying. While the algorithm can be applied to many lossless compression applications, such as document image compression, our primary target application has been lossless compression of integrated circuit layout image data. These images contain a heterogeneous mix of data: dense repetitive data better suited to LZ-style coding, and less dense structured data, better suited to context based encoding. As part of C4, we have developed a novel binary entropy coding technique called combinatorial coding which is simultaneously as efficient as arithmetic coding, and as fast as Huffman coding. Compression results show C4 outperforms JBIG, ZIP, BZIP2, and 2D-LZ, and achieves lossless compression ratios greater than 22 for binary layout image data, and greater than 14 for grey-pixel image data.
1.1 Introduction

For a next-generation 45-nm lithography system, using 25 nm, 5-bit grey pixels, a typical image of only one layer of a 2 cm $\times$ 1 cm chip represents 1.6 terabits of data. A direct-write maskless lithography system with the same specifications requires data transfer rates of 10 terabits per second in order to meet the current industry production throughput of one wafer per layer per minute [1]. These enormous data sizes, and data transfer rates, motivate the application of lossless data compression to VLSI layout data.

VLSI designs produced by microchip designers consist of multiple layers of 2-D polygons stacked vertically, representing wires, transistors, etc. For pixel-based lithography writers, each layer is converted to a 2-D image. Pixels may be binary or grey depending on the design of the writer. A sample of such an image is shown in Figure 1.1.

These lithography images differ from natural or even document images in several important ways. They are synthetically generated, highly structured, follow a rigid set of design rules, and contain highly repetitive regions of common structure.

Our previous experiments [2, 3] have shown that Lempel-Ziv (LZ) style copying [4], used in ZIP, results in high compression ratios on dense, repetitive circuits, such as arrays of memory cells. However, where these repetitions do not exist, such as control logic circuits, LZ-copying does not perform as well. In contrast, context-based prediction [5], used in JBIG [6], captures the local structure of lithography data, resulting in good compression ratios on non-repetitive circuits, but it fails to take advantage of repetitions, where they exist.

We have combined the advantages of LZ-copying and JBIG context-modeling into a new lossless image compression technique called Context Copy Combinatorial Coding (C4). C4 is a single compression technique which performs well for all types of layout: repetitive, non-repetitive, or
a heterogeneous mix of both. In addition, we have developed hierarchical
combinatorial coding (HCC) as a low-complexity alternative to arithmetic coding [7] to be used within C4.

Section 1.2 describes the overall structure of C4. Section 1.3 describes
the context-based prediction model used in C4. Section 1.4 describes LZ-
copying in two dimensions and how the C4 encoder segments the image
into regions using LZ-copying and context-based prediction. Section 1.5
describes HCC used to code prediction errors. Section 1.6 describes the
extension of C4 to grey-pixel layout image data. Section 1.7 includes the
compression results of C4 in comparison to other existing compression tech-
niques for integrated circuit layout data.

1.2 Overview of C4

The basic concept underlying C4 compression is to integrate the advantages
of two disparate compression techniques: local context-based prediction
and LZ-style copying. This is accomplished by automatic segmentation of
the image into copy regions and prediction regions. Each pixel inside a
copy region is copied from a pixel preceding it in raster-scan order. Each
pixel inside a prediction region, i.e. not contained in any copy region,
is predicted from its local context. However, neither predicted values nor
copied values are 100% correct, so error bits are used to indicate the position
of these prediction or copy errors. These error bits can be compressed
using any binary entropy coder, but in C4, we apply our own hierarchical
combinatorial coding (HCC) technique as a low-complexity alternative to
arithmetic coding. Only the copy regions and compressed error bits are
transmitted to the decoder.

In addition, for our application to direct-write maskless lithography, the
C4 decoding algorithm must be implemented in hardware as a parallel array
of thousands of C4 decoders fabricated on the same integrated-circuit chip
as a massively parallel array of writers [3]. As such, the C4 decoder must
have a low implementation complexity. In contrast, the C4 encoder is under
no such complexity constraint. This basic asymmetry in the complexity
requirement between encoding and decoding is central to the design of the
C4 algorithm.

Figure 1.2 shows a high-level block diagram of the C4 encoder and de-
coder for binary layout images. First, a prediction error image is generated
from the layout, using a simple 3-pixel context-based prediction model.
Next, the resulting error image is used to determine the segmentation map
between copy regions and the prediction region, i.e. the set of pixels not
contained in any copy region. As specified by the segmentation map, the
Predict/Copy block estimates each pixel value, either by copying or by pre-
diction. The result is compared to the actual value in the layout image. Correctly predicted or copied pixels are indicated with a “0”, and incorrectly predicted or copied pixels are indicated with a “1”, equivalent to a Boolean XOR operation. These error bits are compressed without loss by the HCC encoder, which are transmitted to the decoder, along with the segmentation map.

The decoder mirrors the encoder, but skips the complex steps necessary to find the segmentation map, which are received from the encoder. Again as specified by the segmentation, the Predict/Copy block estimates each pixel value, either by copying or by prediction. The HCC decoder decompresses the error bits from the encoder. If the error bit is “0” the prediction or copy is correct, and if the error bit is “1” the prediction or copy is incorrect and must be inverted, equivalent to a Boolean XOR operation. Since there is no data modeling performed in the C4 decoder, it is considerably simpler to implement than the encoder, satisfying one of the requirements of our application domain.

1.3 Context-based Prediction Model

For our application domain, i.e. integrated-circuit layout compression, we choose a simple 3-pixel binary context-based prediction model to use in C4, much simpler that the 10-pixel model used in JBIG. Nonetheless, it captures the essential “Manhattan” structure of layout data, as well as some design rules, as seen in Table 1.1.

The pixels used to predict the current coded pixel are the ones above, left, and above-left of the current pixel. The first column shows the 8 possible 3-pixel contexts, the second column shows the prediction, the third column shows what a prediction error represents, and the fourth column shows the empirical prediction error probability for an example layout. From these results, it is clear that the prediction mechanism works extremely well; visual inspection of the prediction error image reveals that prediction errors primarily occur at the corners in the layout. The two exceptional 0% error cases in rows 5 and 6 represent design rule violations. To generate the prediction error image, each correctly predicted pixel is marked with a “0”, and each incorrectly predicted pixel is marked with a “1”, creating a binary image which can be compressed with a standard binary entropy coder. The fewer the number of incorrect predictions, the higher the compression ratio achieved. An example of non-repetitive layout for which prediction works well is shown in Figure 1.3(a), and its corresponding prediction error image is shown in Figure 1.3(b).

In contrast to the non-repetitive layout shown in Figure 1.3(a), some layout image data contains regions that are visually “dense” and repetitive. An example of such a region is shown in Figure 1.4(a). This visual “denseness” results in a dense, large number of prediction errors as seen
Figure 1.3: Non-repetitive layout image data and its resulting prediction error image.

Figure 1.4: Dense repetitive layout image data and its resulting prediction error image.
clearly in the prediction error image in Figure 1.4(b).

The high density of prediction errors translates into low compression ratios using prediction alone. In C4, areas of dense repetitive layout are covered by copy regions to reduce the number of errors, as described in Section 1.4.

1.4 Copy Regions and Segmentation

As seen in Figure 1.4(a) of the previous section, some layout images are highly repetitive. We can take advantage of this repetitiveness to achieve compression by specifying copy regions, i.e. a rectangular region that is copied from another rectangular region preceding it in raster-scan order. In the remainder of this section, we describe the procedure the C4 encoder uses to find these copy regions.

An example of a copy region is shown in the dashed rectangle in Figure 1.5. As seen, a copy region is specified with six copy parameters: position of the upper left corner $x,y$, width $w$, height $h$, distance to the left to copy from $dx$, and distance above to copy from $dy$. For the copy region in Figure 1.5, every pixel inside the region is copied from $dx$ pixels to its left, and $dy = 0$. Although the entire region is copied, the copy itself need not be 100% correct. Similar to the prediction error map, there is a corresponding copy error map within the copy region. Each correctly copied pixel is indicated with a “0”, and each incorrectly copied pixel is marked with a “1”, creating a binary sub-image which can be compressed with a standard binary entropy coder.
As described in Section 1.2, the C4 encoder automatically segments the image into copy regions and the prediction region, i.e., all pixels not contained in any copy region. Each copy region has its own copy parameters and corresponding copy error map, and the background prediction region has a corresponding prediction error map. Together, the error maps merge to form a combined binary prediction/copy error map of the entire image, which is compressed using hierarchical combinatorial coding (HCC) as a binary entropy coder. The lower the number of the total sum of prediction and copy errors, the higher the compression ratio achieved. However, this improvement in compression by the introduction of copy regions, is offset by the cost in bits to specify the copy parameters \((x, y, w, h, dx, dy)\) of each copy region. Moreover, copy regions that overlap with each other are undesirable: each pixel should only be coded once, to save as many bits as possible.

Ideally, we would like the C4 encoder to find the set of non-overlapping copy regions, which minimizes the sum of number of compressed prediction/copy error bits, plus the number of bits necessary to specify the parameters of each copy region. An exhaustive search over this space would involve going over all possible non-overlapping copy region sets, a combinatorial problem, generating the error bits for each set, and performing HCC compression on the error bits. This is clearly infeasible. To make the problem tractable, a number of simplifying assumptions and approximate metrics are adopted.

First we use entropy as a heuristic to estimate the number of bits generated by the HCC encoder to represent error pixels. If \(p\) denotes the percentage of prediction/copy error pixels over the entire image, then error pixels are assigned a per-pixel cost of \(C = -\log_2(p)\) bits, and correctly predicted or copied pixels are assigned a per-pixel cost of \(-\log_2(1-p)\approx 0\). Of course, given a segmentation map, \(p\) can be easily calculated by counting the number of prediction/copy error bits; at the same time, \(p\) affects how copy regions are generated in the first place, as discussed shortly. In C4, we solve this chicken and egg problem by first guessing a value of \(p\), finding a segmentation map using this value, counting the percentage of prediction/copy error pixels, and using this percentage as a new value for \(p\) as input to the segmentation algorithm. This process can be iterated until the guess \(p\) matches the percentage of error pixels, but in practice we find that one iteration is sufficient if the starting guess is reasonable. Empirically, we have found a good starting guess to be the percentage of error pixels when no copy regions are used, then discounted by a constant factor, e.g., a factor of 4.

Next, for any given copy region, we compare the cost, in bits, of coding that region using copy, versus the cost of coding the region using prediction.
If the cost of copying is lower, then the amount by which it is lower is the \textit{benefit} of using this region. The cost of copying is defined as the sum of the cost of describing the copy parameters, plus the cost of coding the copy error map. For our particular application domain, the description cost is 51 bits. Here we have restricted \( x, y, w, h \) to 10-bits each which is reasonable for our \( 1024 \times 1024 \) test images. In addition, we assume that copies are either from above, or to the left, so \((dx, dy)\) is replaced by \((\text{left}/\text{above}, d)\) and represented with 11 bits, where \( d \), represented by 10 bits, denotes the distance left or above to copy from, and \( \text{left}/\text{above} \), represented by 1 bit, denotes the direction left or above to copy from. This assumption is in line with the Manhattan structure of layout data. The cost of coding the copy error map is estimated as \( C \times E_\text{copy} \), where \( C \) denotes the estimated per-pixel cost of an error pixel, as discussed previously, and \( E_\text{copy} \) denotes the number of copy error pixels in the region. Correctly copied pixels are assumed to have 0 cost, as discussed previously. So the total cost of copying is \( 51 + C \times E_\text{copy} \).

The cost of coding the region using prediction is the cost of coding the prediction error map of that region. It is estimated as \( C \times E_\text{context} \), where \( E_\text{context} \) denotes the number of prediction error pixels in the region. Finally, the \textit{benefit} of a region is the difference between these two costs, \( C \times (E_\text{context} - E_\text{copy}) \) \(- 51 \). Note that it is possible for a region to have negative benefit if \( E_\text{context} - E_\text{copy} \leq (51/C) \). The threshold \( T = (51/C) \) is used to quickly disqualify potential copy regions in the search algorithm presented below.

Using benefit as a metric, the optimization goal is to find the set non-overlapping copy regions, which maximizes the sum of benefit over all regions. This search space is combinatorial in size, so exhaustive search is prohibitively complex. Instead we adopt a greedy approach, similar to that used in the 2D-LZ algorithm described in [3]. The basic strategy used by the \textit{find copy regions} algorithm in Figure 1.2 is as follows: start with an empty list of copy regions; and in raster-scan order, add copy regions of maximum benefit, that do not overlap with regions previously added to the list. The completed list of copy regions is the \textit{segmentation} of the layout. A detailed flow diagram of the \textit{find copy regions} algorithm is shown in Figure 1.6, and described in the remainder of this section.

In raster-scan order, we iterate through all possible \((x, y)\). If \((x, y)\) is inside any region in the \textit{segmentation} list, we move on to the next \((x, y)\); otherwise, we iterate through all possible \((\text{left}/\text{above}, d)\). Next for a given \((x, y, \text{left}/\text{above}, d)\), we maximize the size of the copy region \((w, h)\) with the constraint that a \textit{stop pixel} is not encountered; we define a \textit{stop pixel} to be any pixel inside a region in the \textit{segmentation} list, or any pixel with a copy error. These conditions prevent overlap of copy regions, and prevent the
Figure 1.6: Flow diagram of the find copy regions algorithm.
occurrence of copy errors, respectively. Later, we describe how to relax this latter condition to allow for copy errors. The process of finding maximum size copy regions \((w, h)\), is discussed in the next paragraph. Finally, we compute the benefit of all the maximum sized copy regions, and, if any region with positive benefit exists, we add the one with the highest positive benefit to the segmentation list.

We now describe the process of finding the maximum size copy region \((w, h)\). For any given \((x, y, left/above, d)\) there is actually a set of maximum size copy regions, bordered by stop pixels, because \((w, h)\) is a two-dimensional quantity. This is illustrated in the example in Figure 1.7. In the figure, the position of the stop pixels are marked with \(\otimes\) and three overlapping maximum copy regions are shown \((x, y, w_1, h_1)\) \((x, y, w_2, h_2)\) and \((x, y, w_3, h_3)\). The values \(w_1, h_1, w_2, h_2, w_3,\) and \(h_3\) are found using the following procedure: initialize \(w = 1, h = 1\). Increment \(w\) until a stop pixel is encountered; at this point \(w = w_1\). Next increment \(h\), and for each \(h\) increment \(w\) from 1 to \(w_1\), until a stop pixel is encountered; at this point \(h = h_1, w = w_2\). Again increment \(h\), and for each \(h\) increment \(w\) from 1 to \(w_2\), until a stop pixel is encountered; at this point \(h = h_2, w = w_3\). Finally, increment \(h\), and for each \(h\) increment \(w\) from 1 to \(w_3\), until a stop pixel is encountered; at this point \(h = h_3, w = w_4\). The maximum size algorithm is terminated when a stop pixel is encountered at \(w = 1\).

As stated previously, any pixel inside a region in the segmentation list, and any pixel with a copy error, is a stop pixel. The latter condition prevents any copy errors inside a copy region. We relax this condition to merge smaller, error free, copy regions, into larger copy regions with a few number of copy errors. The basic premise is to tradeoff the 51-bits necessary to describe a new copy region against the introduction of bits needed to code copy errors, by excluding some copy error pixels from being stop pixels. For each copy error pixel, we look at a window of \(W\) pixels in a row, where the left most pixel is the copy error. If, in that window, the number of copy
errors is less than the average number of errors expected, $E_{\text{copy}} < W p$, and
the number of copy errors is less than the number of prediction errors, $E_{\text{copy}} < E_{\text{predict}}$, then pixel with the copy error no longer considered to be a stop pixel. The size of the look-ahead window $W$ is a user-defined input parameter to the C4 algorithm. Larger values of $W$ correspond to fewer, larger copy regions, at the expense of increasing the number of copy errors.

1.5 Hierarchical Combinatorial Coding

We have proposed and developed combinatorial coding (CC) [7] as an alternative to arithmetic coding to encode the error bits in Figure 2. The basis for CC is universal enumerative coding [8] which works as follows. For any binary sequence of known length $N$, let $k$ denote the number of ones in that sequence. $k$ ranges from 0 to $N$, and can be encoded using a minimal binary code [11], i.e. a simple Huffman code for uniform distributions, using $\lceil \log_2(N+1) \rceil$ bits. There are exactly $C(N,k) = N!/(N-k)!k!$ sequences of length $N$ with $k$ ones, which can be hypothetically listed. The index of our sequence in this list, known as the ordinal or rank, is an integer ranging from 1 to $C(N,k)$, which can again be encoded using a minimal binary code, using $\lceil \log_2 C(N,k) \rceil$ bits. Enumerative coding is theoretically shown to be optimal [8] if the bits to be compressed are independently and identically distributed (i.i.d.) as $\text{Bernoulli}(\theta)$ where $\theta$ denotes the unknown probability that “1” occurs, which in C4, corresponds to the percentage of error pixels in the prediction/copy error map. The drawback of computing an enumerative code directly is its complexity: the algorithm to find the rank corresponding to a particular binary sequence of length $N$, called ranking in the literature, is $O(N)$ in time, is $O(N^3)$ in memory, and requires $O(N)$ bit precision arithmetic [8].

In CC, this problem is addressed by first dividing the bit sequence into blocks of fixed size $M$. For today’s 32-bit architecture computers, $M = 32$ is a convenient and efficient choice. Enumerative coding is then applied separately to each block, generating a $(k, \text{rank})$ pair for each block. Again, using the same assumption that input bits are i.i.d. as $\text{Bernoulli}(\theta)$, the number of ones $k$ in a block of $M$ bits are i.i.d. as $\text{Binomial}(M, \theta)$. Even though the parameter $\theta$ is unknown, as long as the Binomial distribution is not too skewed, e.g. $0.01 < \theta < 0.99$, a dynamic Huffman code efficiently compresses the $k$-values with little overhead, because the range of $k$ is small. Given there are $k$ ones in a block of $M$ bits, the rank remains uniformly distributed, as in enumerative coding. Therefore, rank-values are efficiently coded using a minimum binary code.

The efficiency of CC, as described, is on par with arithmetic coding, except in cases of extremely skewed distributions, e.g. $\theta < 0.01$. In these
Figure 1.8: 2-level HCC with a block size $M = 4$ for each level.

cases, the probability that $k = 0$ approaches 1 for each block, causing the Huffman code to be inefficient. To address this issue, we have developed an extension to CC called hierarchical combinatorial coding (HCC). It works by binarizing sequence of $k$-values such that $k = 0$ is indicated with a “0” and $k = 1$ to 32 is indicated with a “1”, CC is then applied to the binarized sequence of “0” and “1”, and the value of $k$, ranging from 1 to 32 in the “1” case, is Huffman coded. Clearly, this procedure of CC encoding, binarizing the $k$-values, then CC encoding again can be recursively applied in a hierarchical fashion, to take care of any inefficiencies in the Huffman code for $k$-values, as $\theta$ approaches 0.

Figure 1.8 is an example of HCC in action with 2-levels of hierarchy and block size $M = 4$. Only values in bold italics are coded and transmitted to the decoder. Looking at rows from bottom to top, the original data is in the lowest row labeled “bits - level 0”. Applying CC with $M = 4$, the next two rows show the rank and $k$ value for each block in level 0. Note that when $k = 0$ no rank value is needed as indicated by the hyphen. The high frequency of $0$ in “$k$ - level 0” makes it inefficient for coding directly using Huffman coding. Instead, we binarize “$k$ - level 0”, to form “bits - level 1”, using the binarization procedure described in the previous paragraph. CC is recursively applied to “bits - level 1”, to compute “rank - level 1” and “$k$ - level 1”. Finally, to code the data, “$k$ - level 1” is coded using a Huffman code, “rank - level 1” is coded using a minimal binary code, non-zero values of “$k$ - level 0” are coded using a Huffman code, and “rank - level 0” is coded using a minimal binary code.

The rationale for choosing Huffman coding and minimal binary coding is the same as CC. If the input is assumed to be i.i.d. as $Bernoulli(\theta)$, all level rank-values are uniformly distributed, given the corresponding $k$-
values in the same level. Furthermore, although the exact distribution of $k$-values is unknown, a dynamic Huffman code can adapt to the distribution with little overhead, because the dynamic range of $k$ is small. Finally, for highly skewed distributions of $k$, which hurts the compression efficiency of Huffman coding, the binarization process reduces the skew by removing the most probable symbol $k = 0$.

Studying the example in Figure 1.8, we can intuitively understand the efficiency of HCC: the single Huffman coded $0$ in “$k$ – level 1” decodes to $M^2$ zeroes in “bits - level 0”. In general, for $L$-level HCC, a single Huffman coded $0$ in level $L - 1$ corresponds to $M^L$ zeroes in “bits - level 0”. HCC’s ability to effectively compress blocks of zeroes is critical to achieving high compression ratios, when the percentage of the error pixels is low.

In addition to achieving efficient compression, HCC also has several properties favorable to our application domain. First, the decoder is extremely simple to implement: the Huffman code tables are small because the range of $k$-values is small, unranking is accomplished with a simple table lookup, comparator, and adder, and minimal binary decoding is also accomplished by a simple table lookup and an adder. Second, the decoder is fast: blocks of $M^{(L+1)}$ zeroes can be decoded instantly when a zero is encountered at level $L$. Third, HCC is easily parallelizable: block sizes are fixed and block boundaries are independent of the data, so the compressed bitstream can be easily partitioned and distributed to multiple parallel HCC decoders. This is in contrast to run-length coding schemes such as Golomb codes [9], which also code for runs of zeroes, but have data-dependent block boundaries.

Independent of our development of HCC, a similar technique called Hierarchical Enumerative Coding (HEC) has been developed in [10]. The main difference between HEC and HCC is the method of coding $k$ values at each level. HCC uses binarization and simple Huffman coding, whereas HEC uses hierarchical integer enumerative coding, which is more complex [10]. In addition, HEC requires more levels of hierarchy to achieve the same level of compression efficiency as HCC. Consequently, HCC is significantly less complex to compute than HEC.

To compare HCC with existing entropy coding techniques, we apply 3-pixel context based prediction as described in Section 1.3 to a 242 kb layout image and generate 8 binary streams. We then apply Huffman coding to blocks of 8-bits, arithmetic coding, Golomb run-length coding, HEC, and HCC to each binary stream, and report the compression ratio obtained by each algorithm. In addition, we report the encoding and decoding times as a measure for complexity of these algorithms. The results are shown in Table 1.2.

Among these techniques, HCC is one of the most efficient in terms of

Figure 1.9: Block diagram of C4 encoder and decoder for grey-pixel images.

compression, and one of the fastest to encode and decode, justifying its use in C4. The only algorithm comparable in both efficiency and speed, among those tested, is Golomb run-length coding. However, as previously mentioned, HCC has fixed, data-independent block boundaries, which are advantageous for parallel hardware implementations; run-length coding does not. Run-times are reported for 100 iterations on an 800 MHz Pentium III workstation. All algorithms are written in C# and optimized with the assistance of VTune to eliminate bottlenecks. The arithmetic coding algorithm is based on that described in [11].
Chapter 1

Figure 1.10: 3-pixel linear prediction with saturation used in grey-pixel C4.

1.6 Extension to Grey Pixels

So far, C4 as described is a binary image compression technique. To extend C4 to encode 5-bit grey-pixel layout image, slight modifications need to be made to the prediction mechanism, and the representation of the error. Specifically, the local 3-pixel context based prediction described in Section 3, is replaced by 3-pixel linear prediction with saturation, to be described later; furthermore, in places of prediction or copy error, where the error bit is “1”, an error value indicates the correct value of that pixel. A block diagram of the C4 encoder and decoder for grey-pixel images is shown in Figure 1.9.

First, a prediction error image is generated from the layout, using a simple 3-pixel linear prediction model. The error image is a binary image, where “0” denotes a correctly predicted grey-pixel value and “1” denotes a prediction error. The copy regions are found as before in binary C4, with no change in the algorithm. As specified by the copy regions, the Predict/Copy generates pixel values either using copying or linear prediction. The result is compared to the actual value in the layout image. Correctly predicted or copied pixels are indicated with a “0”, and incorrectly predicted or copied pixels are indicated with a “1” with an error value generated indicating the true value of the pixel. The error bits are compressed with a HCC encoder, and the actual error values are compressed with a Huffman encoder.

As in binary C4, the grey-pixel C4 decoder mirrors the encoder, but skips the complex steps necessary to find the copy regions. The Predict/Copy block generates pixel values either using copying or linear prediction according to the copy regions. The HCC decoder decodes the error bits, and the Huffman decoder decodes the error values. If the error bit is “0” the prediction or copy is correct, and if the error bit is “1” the prediction or copy is incorrect and the actual pixel value is the error value.

The linear prediction mechanism used in grey-pixel C4 is analogous to the context-based prediction used in binary C4. Each pixel is predicted from its 3-pixel neighborhood as shown in Figure 1.10. “?” is predicted as a linear combination of its local 3-pixel neighborhood “a”, “b”, and “c”. If the prediction value is negative or exceeds the maximum allowed pixel

\[
x = b - a + c
\]

if \(x < 0\) then \(? = 0\)

if \(x > \text{max}\) then \(? = \text{max}\)

otherwise \(? = x\)
value $\max$, the result is clipped to 0 or $\max$ respectively. Interestingly, this linear predictor can also be applied to a binary image by setting $\max = 1$, resulting in the same predicted values as binary context-based prediction described in Section 3. It is also similar to the median predictor used in JPEG-LS [13].

We apply a suite of existing and general lossless compression techniques as well as C4 to binary layout image data. Compression results are listed in Table 1.3. The original data are 2048×2048 binary images with 300 nm pixels sampled from an industry microprocessor layout, which corresponds to a 0.61 mm by 0.61 mm section, covering about 0.1% of the chip area. Each entry in the table corresponds to the compression ratio for one such image.

The first column “Type” indicates where the sample comes from, memory, control, or a mixture of the two. Memory circuits are typically extremely dense but highly repetitive. In contrast, control circuits are highly irregular, but typically much less dense. The second column “Layer” indicates which layer of the chip the image comes from. Poly and Metal1 layers are typically the densest, and mostly correspond to wire routing and formation of transistors. The remaining columns from left to right are compression ratios achieved by: JBIG, ZIP, 2D-LZ, our 2D extension to the LZ77 copying [3], BZIP2 based on the Burrows-Wheeler Transform [12], and C4. The bold numbers indicate the highest compression for each row.

As seen, C4 outperforms all these algorithms for all types of layouts. This is significant, because most layouts contain a heterogeneous mix of memory and control circuits. ZIP, 2D-LZ and BZIP2 take advantage of repetitions resulting in high compression ratios on memory cells. In con-
contrast, where the layout becomes less regular, the context modeling of JBIG has an advantage over ZIP, 2D-LZ, and BZIP2.

Table 1.4 is compression results for more modern layout image data with 65 nm pixels and 5-bit grey layout image data. For each layer, 5 blocks of 1024 x 1024 pixels are sampled from two different layouts, 3 from the first, and 2 from the second, and the minimum compression ratio achieved for each algorithm over all 5 samples is reported. The reason for using minimum rather than the average has to do with limited buffering in the actual hardware implementation of maskless lithography writers. Specifically, the compression ratio must be consistent across all portions of the layout as much as possible. From left to right, compression ratios are reported in columns for a simple run-length encoder, Huffman encoder, LZ77 with a history buffer length of 256, LZ77 with a history buffer length of 1024, ZIP, BZIP2, and C4. Clearly, C4 still has the highest compression ratio among all these techniques. Some notable lossless grey-pixel image compression techniques have been excluded from this table including SPIHT and JPEG-LS. Our previous experiments in [2] have already shown that they do not perform well as simple ZIP compression on this class of data.

In Table 1.5, we show results for 10 sample images from the data set used to obtain Table 1.4, where each row is information on one sample image. In the first column “Type”, we visually categorize each sample as repetitive, non-repetitive, or containing a mix of repetitive and non-repetitive regions. The second column is the chip layer from which the sample is drawn. The third column “LP” is the compression ratio achieved by linear prediction alone, equivalent to C4 compression with copy regions disabled. The fourth and fifth columns are the compression ratio achieved by ZIP and the full C4 compression respectively. The last column “Copy%” is the percent of the total sample image area covered by copy regions, when C4 compression is

applied. Any pixel of the image not covered by copy regions is, by default, linearly predicted from its neighbors.

Clearly, the Copy% varies dramatically from image to image ranging from 18% to 99% across the 10 samples, testifying to C4’s ability to adapt to different types of layouts. In general a high Copy% corresponds to repetitive layout, and low Copy% corresponds to non-repetitive layout. Also, the higher the Copy%, the more favorably ZIP compares to LP compression. This agrees with the intuition that LZ-style techniques work well for repetitive layout, and prediction techniques work well for non-repetitive layout. At one extreme, in the non-repetitive-M1 row, where 18% of the image is copied in C4, LP’s compression ratio exceeds ZIP. At the other extreme, in the repetitive-Poly row, where 99% of the image is copied, ZIP’s compression ratio is more than 3 times that of LP. This trend breaks down when the compression becomes high for both LP and ZIP, e.g. the rows labeled Mixed-N and Mixed-P. These layouts contain large featureless areas, which are easily compressible by both copying and prediction. In these cases, C4 favors using prediction to avoid the overhead of specifying copy parameters.

1.8 Summary

C4 is a novel compression algorithm, which successfully integrates the advantages of two very disparate compression techniques: context-based modeling and LZ-style copying. This is particularly important in the context of layout image data compression which contains a heterogeneous mix of
data: dense repetitive data better suited to LZ-style coding, and less dense structured data, better suited to context based encoding. In addition, C4 utilizes a novel binary entropy coding technique called combinatorial coding which is simultaneously as efficient as arithmetic coding and as fast as Huffman coding. Compression results show that C4 achieves superior compression results over JBIG, ZIP, BZIP2 and 2D-LZ for a wide variety of industry lithography image data.

This research is conducted under the Research Network for Advanced Lithography, supported jointly by SRC (01-MC-460) and DARPA (MDA972-01-1-0021).
